Life Sellustra Project: planning and realization of integrated methods for restoration of the catchment in Val Sellustra

Gumiero Bruna, Conte Giulio, Boz Bruno

ABSTRACT: The "Sellustra Life" project is one of the 19 Italian projects financed in 2001 from the "Life Environment Program". The proponent end beneficiary of this project is the Municipality of Dozza (a town in the central part of Italy) with the scientific collaboration of CIRF (Italian Center for River Restoration). The project appeals to the Public Administrations and offers an example of application of innovative systems at low environmental impact for the control of pollution sources and for the riqualification of river environments and rural landscape.

The objective of the project consists in planning and steering public and private works oriented to manage the sources of pollutants that flow in the Sellustra stream and to improve the environmental value of its banks and of the rural landscape. The purpose is to join productive activities (included farming) with environmental safeguard and sustainable development. The planting of buffer strips, to improve the landscape and to reduce pollution will not be founded directly by Life project but will be encouraged by the activities oriented to farmers that will be carried out.

Others actions directly financed from the project regard the building of constructed wetland and some bioengineering works. Another objective of the project is not to demonstrate the validity of the single techniques but above all to highlight the opportunities of using these integrated techniques for solving different problems (pollution, environment degradation, semplification of landscape).

This project wants to produce a useful "model" for planning remediation projects following a bottom-up strategy that can be reproduced in others geographical areas.

KEYWORDS: river restoration, buffer strips, bioengineering, constructed wetland

Introduction

The general, methodological objective of the project "Planning and implementing integrated methods for environmental restoration of the Val Sellustra basin" was to demonstrate the effectiveness of a new approach to the management and restoration of catchment areas based on orchestration between citizens and public organisations.

From ideation up through implementation, the project strategy was intended to:

- highlight the role that a small municipal administration can assume in promoting initiatives regarding river restoration with respect to superordinate bodies;
- emphasise the importance of starting with in-depth planning at the basin level involving all parties interested in the territory to ensure the design and subsequent implementation of focused and effective measures;
- favour cultural growth and sharing of environmental subjects at a local and regional level;
- successfully implement pilot measures that could act as flywheels in spreading the use of low environmental impact techniques throughout the Sellustra basin as well as in other environments.

The Sellustra Life project was intended to demonstrate that local authorities, due to their greater and more direct knowledge of the territory and its social elements, are in some cases better able to develop participatory processes to allow objectives and intervention methods to be shared with interested parties.

In this way, by understanding the needs of the territory and transferring them to the decision-making process (bottom up strategy), local authorities can become promoters of a more consistent and farsighted policy than typical command and control policies (top down strategy). The project's strategy transpired from the fact that, although the beneficiary of the planned activities was autonomous from the onset, meetings, internal conventions and debates with institutions were promoted in order to present the initiative and stimulate new partnerships, thereby increasing the possibilities of interventions on the Sellustra basin or favouring the reproduction of the experience in different situations.

The aim of the project was also to demonstrate, through improvement of the ecological condition of the Sellustra river, the effectiveness of the integrated application of low-impact techniques such as bioengineering and constructed wetlands.

More specifically, the measures planned as part of the Sellustra Life project were aimed at:

- improving water quality in terms of nonpoint (nitrates from agriculture) and point (outflow discharges from the sewer system) source pollution;
- resolving problems regarding bank erosion through low-impact measures and eliminating or reducing the effects of the intense use of artificial elements in the channel;
- Increasing biodiversity and improving the landscape by restoring the riparian vegetation and recreating habitats, refuges for the fauna and ecological corridors.

The measures implemented

The constructed wetland

The system implemented is a horizontal subsurface flow (SFS-h) system. The waste passes through a gravel bed located on and impermeable basin in which vegetation is planted, and the plants provide the oxygen required for the biological process of nitrification and degradation of the organic matter.

From a functional standpoint, this type of system provides greater purification efficacy per unit area than free water systems.

Since the wastewater level is lower than the surface of the gravel bed, the surface of the wetland remains dry and accessible for maintenance activities, which, moreover, are minimal. Furthermore, the absence of wastewater exposure limits nuisances such as odours or insects.

Dimensioning of the purification system was based on the characteristics of the influent and the established purification objectives, using the most diffused seizing equation available in the international scientific literature to forecast the performance of the system. The sewage system intercepted, which was previously attached to the Sellustra pumping station, collects wastewater for a total of approximately 120 population equivalents (p.e.).

The system implemented provides for primary sewage treatment in Imhoff septic tanks, to treat the gross suspended solids and avoid clogging phenomena at the wetland inlet.

Figura 1 The constructed wetland realized near Sellustra stream

The Imhoff system effluent is divided inside a sump pit and routed to 2 rectangular constructed wetland cells each with a surface area of 180 m (12 m long and 15 m wide), positioned parallel to one another.

The layout of the system was chosen for reasons regarding the area's morphology, to allow better inclusion in the landscape, as well as for its functionality (Figura 1). It allows better distribution of influents, provides a larger crossing area and prevents clogging. In addition, maintenance can be carried out on one of the cells without interrupting system operation.

The beds of the cells are lined in non-woven fabric made of type 250 g/m^2 mineral fibre, which, being biodegradable, is of moderate environmental impact as compared to other alternatives. A continuous layer of natural, easily obtainable sand was placed on top of the non-woven fabric in order to achieve a 1% slope and to provide mechanical protection of the geomembrane from puncture.

To avoid any contact of wastewater with goundwater, black, high-density polyethylene geomembrane (2 mm thick) was used, which offers high mechanical, chemical and physical resistance while having, in this case as well, moderate environmental impact as compared to other alternatives. It also provided considerable ease in shaping during positioning.

The inlet and outlet pipes are polyethylene, easily installable, highly resistant to chemicals and electrolytes and have surfaces that prevent scale build-up. In addition, they adapt well to irregularities in the terrain and, due to their smooth surfaces, provide higher flow rates than traditional piping.

The location of the wetland allows the wastewater flow occur by gravity, avoiding the use of pumps that requires energy.

The drainage system is made of perforated polyethylene piping that enables flows to be drawn from the bottom of the cells, prevents the infiltration of coarse materials and allows backwashing.The cells were filled with round gravel with an average diameter of 8/10 mm, which was thoroughly washed and deposited in a layer of 80 cm average thickness. A level of porosity was chosen that would ensure good hydraulic conductivity, efficient removal by sedimentation and adequate support for the development of bacterial biofilms and macrophyte communities.

The species of plants used are *Phragmites australis*, which have a high capacity for survival in extreme environmental conditions and a good tolerance to influent concentrations. They are proven to be efficient, are readily and economically available and have more extensive root systems than other macrophytes. Plant density is approximately 4 plants/m^2.

Lastly, an embankment was placed around the wetland with a height of 0.33 m, a width of 0.5 m and a slope of approximately 45°. Turfgrass was placed on the banks and protected with a geonet made of jute in order to mitigate the impact of the geomembrane, to allow a layer of terrain to be blocked, to protect the banks from erosion and to prevent soil runoff during heavy rains.

Discharge of the effluent into the receiving body of water occurs after passage through a control sump where the water level is adjusted and samples are taken.

Bioengineering measures

The objectives of the bioengineering measures implemented as part of the project included:

- restore natural conditions of the aquatic ecosystem
- enhancing the landscape and ecological quality of the riparian vegetation strips
- reducing the transport of fine sediment in the channel

In selecting areas to act on, situations were identified that were representative of the overall condition of the river. In this way, generalised implementation methods could be outlined, in keeping with the “pilot” character of the project.

The general approach of the project aimed at reducing the restoration works to the minimum, trying to increase the natural enhanchment capacity of the river itself. Despite its general state of degradation, the channel of the Sellustra presents a varied morphology useful for a rich river ecosystem. Even some areas of the riparian formations are of significant interest, with isolated specimens of arboreal species such as willow trees and poplars.

A generalised reprofiling of the banks would have lead to the loss of these elements and impoverished the channel by making it monotonous. It was therefore decided to act on areas that showed true signs of instability or where the introduction of artificial elements into the channel was particularly accentuated.

For measures regarding vegetation restoration, an effort was made to enhance existing vegetation as much as possible by removing only invasive arboreal vegetation and replanting where coverage had become exceedingly sparse.

The site was identified downstream from the bridge in Via Sellustra, near a pig-breeding farm.

The naturalness of the channel had been particularly damaged in this tract as a result of erosion-halting measures that had been implemented over time.

In addition to the discontinuity caused by the bridge foundation, which created a weir approximately 1 metre high, the river bed is covered with a slab of reinforced concrete, also almost a metre high. The banks are protected with mesh gabions filled with rock that, if removed, would have excessively upset the equilibrium that has been established over time.

The remaining banks showed excessive sloping and the presence of numerous points of active erosion.

The vegetation along the banks was considerably degraded with an abundance of Robinia.

The measures implemented had two distinct goals:

- reducing the artificial elements in the upstream part of the channel;
- finding a more stable physical and ecological conditions for the banks along the remaining tracts.

The discontinuity created by the weir under the bridge was resolved by constructing a ramp out of rocks partially tied with steel cables, at a 10% slope.

Above the cemented area, which would have been too difficult to remove and excessively risky for the area's overall stability, a number of weirs were constructed using stones tied with steel cables or beams anchored to the concrete underneath.

In the portion of the channel downstream from the curve, the banks were reprofiled to provide a more stable slope. In the few bank's sections where riprofiling was not required only restoration of the vegetation was carried out.

The reprofiled bank was protected from erosion at the toe by horizontal or vertical live palisades and, in the lower 2 m portion, with turfgrass protected with a geonet made of jute. Small, deep-rooted, shrubby plant species were planted in the area of the bank above the protected turfgrass in the following proportions:

Euonymus europaeus 20%, *Cornus sanguinea* 30%, *Rosa sempervirens* 15%, *Sambucus nigra* 20%, *Ligustrum vulgare* 15%.

In the area near the river's edge, *Ulmus minor* and *Fraxinus oxycarpa* varieties, ranging from 1.5 to 2.0 m in height, were planted with their rootballs.

Figura 2 The slope built with stone block in order to smooth the drop under the bridge.

The wooded buffer zones

Buffer zones are typically used as best management practices along lower-order streams for enhancement of water quality, protection of fish and wildlife habitat etc. To meet such diverse objectives, riparian zones remove sediment from overland flow, remove and sequester nutrients and other pollutants from overland and shallow subsurface flows, and provide habitat values in the form of streamside shading, generation of coarse and fine particulate matter, and food and cover for wildlife.

The control of nitrate pollution can be realized increasing the complexity of the landscape, not necessarily all over the catchment but in specific zones, especially within the river corridor.

For this reason an important part of the project was the plantation of woody buffer strips near the Sellustra stream and its tributaries.

Plantation of the wooded buffer zones was not included in the Sellustra Life project as an initiative financed by the project itself, but as the result of the activity of territorial animation primarily directed at the farms bordering the river.

It was, in fact, decided to implement measures that were in synergy with the already existing possibilities of financing provided for by the structural funds of the Regional Rural Development Plan, with strategic objectives that included involving regional authorities in the project, making private parties directly responsible for and involving them in restoration of the catchment area and generating a flow of additional resources to the territory.

From an environmental standpoint, the buffer zones contributed to the attainment of objectives regarding improvement of water and landscape quality as well as the containment of erosion along the banks.

The information counter provided farms with the technical assistance necessary for planning the wooded hedges plantation and preparing applications for financing.

A total of four buffer zones were planted during the Life project, three of which were financed by independent private initiatives and one of which was publicly financed.

Evaluation by monitoring activity

Evaluation is an extremely important step in the rehabilitation procedure. With no formal check on the success of a project, it is difficult to improve the techniques we use, because we don’t even know if they need improving. The monitoring involved in evaluation means that damage, or flaws in the project, can be detected and fixed, where otherwise they may have gone unnoticed. Our evaluation approach deal with natural and spatial variability is call BACI (Before-After/Control-Impact). This is an evaluation program with rehabilitation and control sites, with replicate samples taken through time.

Adoption of a basin-level approach imposes that the environmental monitoring activity not be limited to assessing water quality, but that it take other important aspects into consideration as well, including the morphology of the channel, the structure and state of riparian vegetation and the functioning of selected ecological processes.

Each index used is associated with the specific environmental objectives of the project: EBI (Extended Biotic Index), chemical and bacteriological parameters (L.I.M.), SECA (Ecological State of the River), I.F.F. (Index of River Functionality), and Leaf packs. This last one is a method allowing the evaluation of the complex effect of different biochemical water parameters through the measure of decomposition rate of leaves inside water.

The improvement of water quality resulting from implementation of the constructed wetland and buffer strips is measured using the EBI (Extended Biotic Index), macro indicators (L.I.M.) and Leaf packs. Enhancement of the quality of the landscape resulting from the naturalistic engineering measures and buffer strips is evaluated using I.F.F. (Index of River Functionality). The evaluation of the functioning of the fluvial ecosystem was performed using retention capacity and Leaf packs methods.

An integrated evaluation of the LIM and EBI data allows determination of the SECA. For the Sellustra stations, the worst results are those registered by the EBI. The chemical and bacteriological parameters (L.I.M.) have a instantaneous values so they could not measured alterations or occasional or not directly caused by water quality. On the other hands these alterations are well recorded by macroinvertebrate community.

For sure the river restoration realized is not jet adequate to improve water quality. Besides this the extraordinarily dry climatic conditions of the summer 2003 and some temporary and unknown urban and industrial waste impacted water quality. All these natural and artificial unpredictable events hindered the normal performance of the monitoring activities, resulting in the delay of an entire data collection campaign. The post restoration monitoring shows only one improvement and some worsening of class SECA quality.

The rate of decomposition of the leaves is surprisingly fast. The macroinvertebrate functional feeding group of shredders was limited, indicating that the fast rate of decompo-

sition is attributable to the elevate concentrations of nitrogen and phosphorous. These concentrations are important in regulating the process of decomposition in that they cause an increase in the activity of hyphomycete fungi.

As regards the catchment area as a whole and the strong impact of nonpoint pollution on the Sellustra river, it appears that the first pilot buffer zone are insufficient for reducing the river's strong nitrogen and phosphorus concentrations. More significant results would have been achieved if the project's aim, which entailed covering at least 75% of the bonks with buffer zones, including near the drainage ditches in intensely cultivated areas or where manure spreading is practiced.

The naturalistic engineering measures have already begun to show some positive effects, both in terms of increased self-purifying capacity of the stream and, most important, as regards improved overall functioning of the ecosystem. These aspects can be effectively measured using the I.F.F. index. Although a period of at least two years will be required before the ecosystem reached stability and the results can be consolidated, initial analyses of the I.F.F. performed before and after the implementation of measures show significant improvements in all three reaches concerned. The promotion to a higher class is attributable to the improvement of vegetation conditions, better functioning of the banks and increased diversification of the channel morphology.

Conclusion

The experience of the project "Sellustra life" cannot be considered concluded until actions carried out are completely developed, express definitively the foreseen environmental effects and these are measurable. Biological rate of growth of trees and shrubs must be respected and the requested time exceed the end of the project. Nevertheless it is possible and appropriate to produce a first report on the results obtained by the work method adopted within the project:

- It contributed to develop the idea to treat locally watewater and meteoric urban waters, adopting natural system when possible, and return them as soon as possible to water course after cleaning
- It promoted the principles that more natural are the conditions of a river, free of expand and move itself and coupled with a prosperous riparian vegetation, more

safety and convenient is its management and if it is necessary to operate because important values are threatened is better to adopt low impact techniques.

- It showed a correct interpretation of the role of farmers as managers of the environment as established by common and national policies, expecially il suitably supported by financial subsides and also by information activities, training and technical assistance.

Acknowledegements
